(57) Since the distance from the interrogator to the transponder cannot be controlled in many RF-ID applications, a time or power control over the interrogation pulse is provided to eliminate transponder heat-up. The RF\_ID system transmits a narrow interrogation pulse, for example of 5 msec duration and then monitors for an even shorter duration, for example 1 msec, for a transponders response signal. The monitoring duration is maintained a minimum to create the most efficient charge-up system. Upon the absence of the transponders response signal, the interrogator increases the interrogation pulse duration in steps, until the receiver in the interrogator detects a response signal. A response signal indicates that the transponder has received enough power from the interrogation signal, represented as a voltage stored on a capacitor located in the transponder. This system can be supported by transponders which have no discharge function, to allow the transponders to achieve the final charge-up voltage level with a series of combined short duration power pulses, or by transponders which have discharge functions and which must wait for an adequate duration interrogation pulse to receive enough voltage. Alternatively, instead of increasing the duration of the interrogation pulses, the amplitude of the

interrogation pulses can be increased to produce a similar increase in the amount of interrogation power transmitted.

*Fig.1*

## Field of the Invention

This invention relates to radio-frequency identification systems which operate with sequential power/read functions.

## Background of the Invention

Radio-frequency identification systems with interrogator sequential power/read functions, operate over a large dynamic range with regard to field strength levels. This phenomena stems from the fact that the largest required reading range of any given read area defines the power level in conjunction with the predetermined time window. If an RF-ID system is designed for maximum range, the close-proximity field strength is very high for the transponders nearest the interrogator. In such cases, transponders may be heated up by the over-voltage protection circuit which is absorbing excessive power in near field conditions. The second negative effect is that most of the charge-up pulse is wasted for the closest transponders. If, for example, a power pulse must be 50 milliseconds in length to charge the furthest transponder, but the closest transponder requires only .5 milliseconds to obtain sufficient energy to return a reply, the other 49.5 milliseconds of the power pulse is wasted on the closest transponders.

The over-charging problem is especially disadvantageous in temperature sensor applications. In such applications, an accurate temperature measurement may not be obtainable because the transponder eventually dissipates the extra power pulse energy in the surrounding area of the sensor, which is typically in the temperature measurement vicinity. Over-charging can cause the temperature of the transponder to rise anywhere from 20-80 C, depending upon the required reading range and/or the transponders distance from the interrogator, thereby causing enormous errors in the temperature measurement readings.

The duration or the amplitude of the interrogation power pulse, thus the energy consumption and heating-up of the transponder, as well as the energy consumption of the interrogation unit can be optimized by the proposed invention.

## Summary of the Invention

Since the distance from the interrogator to the transponder cannot be controlled in many RF-ID applications, a time or power control over the interrogation pulse is provided to eliminate transponder heat-up. The RF\_ID system according to a preferred embodiment of this invention transmits a narrow interrogation pulse, for example of 5 msec duration and then monitors for an even shorter

duration, for example 1 msec, for a transponders response signal. The monitoring duration is maintained a minimum to create the most efficient charge-up system. Upon the absence of the transponders response signal, the interrogator increases the interrogation pulse duration in steps, until the receiver in the interrogator detects a response signal. A response signal indicates that the transponder has received enough power from the interrogation signal, represented as a voltage stored on a capacitor located in the transponder. This system can be supported by transponders which have no discharge function, to allow the transponders to achieve the final charge-up voltage level with a series of combined short duration power pulses, or by transponders which have discharge functions and which must wait for an adequate duration interrogation pulse to receive enough voltage. Alternatively, according to a second embodiment, instead of increasing the duration of the interrogation pulses, the amplitude of the interrogation pulses can be increased to produce a similar increase in the amount of interrogation power transmitted.

Moreover, according to one embodiment, when more than one transponder is within an interrogation read range, after a transponder has sent a response message back to the interrogator, that transponder is inactivated for a predetermined amount of time to allow the rest of the transponders in the read range to respond to an interrogation pulse.

#### Detailed Description of the Preferred Embodiments

A block diagram of an interrogator is shown in Figure 1. According to a first preferred embodiment, an oscillator 10 of the interrogator 9, commanded by a microprocessor not shown, sends a signal through a variable amplifier 12 to a coupler 14, where the amplified interrogation signal resonates the parallel resonant combination 16 and is transmitted via the antenna 18. The first interrogation signal transmitted is a short power pulse, for example, 5 milliseconds, which is shorter in pulse duration than would be required to power up the most distant transponder. The receiver 20 of the interrogator 9 then listens for a short, predetermined time period, for example, 1 millisecond, for a transponders response signal. If the receiver 20 does not detect a response during the predetermined listening time period, it sends a control signal to the Pulse Width Control Circuitry 21. According to one embodiment, the Pulse Width Control Circuitry 21 includes a data control circuit 22 which receives the control signal from receiver 20, and in turn sends a signal to the time duration control circuit 24 to increase the duration of the interrogation pulse. The interrogator 9 continues a cycle of sending successively longer duration interrogation pulses and monitoring for a transponders response until the receiver 20 in the interrogator 9 detects the presence of a transponders response signal, thereby signifying an adequate charge-up power level in the transponder.

In another embodiment according to the invention shown in Figure 8, instead of controlling the duration of the interrogation pulse with Pulse Width Control Circuitry 21, the amplitude of the interrogation signal could be controlled with a Power Control Circuit 27 which increases the amplitude of the interrogation pulse in successive steps. In the same method as described above, an oscillator 10 of the interrogator 9, commanded by a micropro-

cessor not shown, sends a signal through a variable amplifier 12 to a coupler 14, where the amplified interrogation signal resonates the parallel resonant combination 16 and is transmitted via the antenna 18. The first interrogation signal transmitted is a low power pulse, for example, 5 mW, which is less in amplitude than would be required to power up the most distant transponder. The receiver 20 of the interrogator 9 then listens for a short, predetermined time period, for example, 1 millisecond, for a transponders response signal. If the receiver 20 does not detect a response during the predetermined listening time period, it sends a control signal to the Amplitude Control Circuitry 29. According to one embodiment, the Amplitude Control Circuitry 21 includes a data control circuit 22 which receives the control signal from receiver 20, and in turn sends a signal to the amplitude control circuit 24 to increase the amplitude of the interrogation pulse. The interrogator 9 continues a cycle of sending successively higher amplitude interrogation pulses, as shown in Figure 10, and monitoring for a transponders response until the receiver 20 in the interrogator 9 detects the presence of a transponders response signal, thereby signifying an adequate charge-up power level in the transponder.

In either embodiment, the interrogation pulse is received by antenna 26 of the resonant circuit 28 which resonates with the interrogation signal frequency in the transponder 25 shown in Figure 2. The interrogation pulse is rectified by the diode 30 and the voltage stored in energy storage element 32. Circuit element 38 generates the transponder response signal in response to the termination of the interrogation pulse and a voltage level representative of a predetermined amount of power received from the interrogation pulse signal. The termination of the interrogation pulse is detected in the transponder by an RF threshold detector, which is not shown, when the amplitude of the RF oscillation at the resonant circuit 28 has dropped below a predetermined level. Therefore, for transponders 25 with no discharge function, the interrogation pulses are received, rectified and stored such that, if the received pulses do not translate into enough power to enable a response, the transponder 25 substantially maintains the current voltage level and waits for another interrogation pulse. On the other hand, for a transponder 25 with a discharge function, the interrogation pulse is received, rectified and stored such that, if the received pulse does not translate into enough voltage to enable a response, the transponder 25 is discharged and must wait for a longer duration pulse. The difference between charging a transponder 25 with a discharge function and charging a transponder 25 without a discharge function, located the same distance from an interrogator 9, is that the transponder 25 with no

discharge function can charge-up to the required voltage with a series of short duration, or low amplitude pulses and the transponder 25 with a discharge function must wait for a longer duration, or higher amplitude interrogation pulse.

As an illustration of the variable duration interrogation pulse preferred embodiment, the task of locating a single transponder which has a discharge function is addressed. An interrogation pulse of short duration is transmitted initially from the antenna 18 of interrogator 9. Then, receiver 20 listens for a predetermined time period, much shorter than the duration of the interrogation pulse, and upon the absence of a transponders response signal, Pulse Width Control Circuit 24 increases the duration of the interrogation pulse. Although the transponder 25 has not responded, signifying storage of an insufficient amount of interrogation signal energy, the transponder 25 may have stored some energy from the interrogation signal, simply not enough to transmit a response signal. However, because the transponder 25 has a discharge function, as soon as the transponder acknowledges that the interrogation signal has terminated and there is an inadequate amount of energy stored, transponder 25 discharges. Therefore, to charge-up transponder 25, an interrogation pulse of the same duration as the first interrogation pulse would not suffice. The transmission of a longer duration interrogation pulse, as transmitted by the interrogator 9 of Figure 1 would be necessary. Thus, the interrogator 9 continues to send longer and longer duration interrogation pulses until the interrogator detects the presence of a transponders response signal. In this way, the transponder is charged to the required voltage without heating up with excess interrogation signal energy. In another embodiment of the invention, the transponder 25 does not have a discharge function. Therefore, a series of interrogation pulses having the same duration may also charge-up the transponder 25 to the required voltage also without causing the transponder 25 to heat up with excess interrogation signal energy.

One of the greatest advantages offered by the interrogator transmitting a series of short duration, lower power interrogation pulses versus very long duration, very high power interrogation pulses is realized in a remote temperature measurement system. Transponders 25 which have temperature measurement sensors, are prone to inaccurate temperature readings in a standard RF-ID system which continually transmits an interrogation pulse of adequate duration to charge-up the furthest transponder. By transmitting a minimum duration interrogation signal, followed by successively longer interrogation pulses, transponders with temperature sensors can achieve more accurate temperature measurements. For example, in a prior-art remote

temperature sensor system, a transponder receives, stores and rectifies the interrogation signal and upon a detected decrease in the power level of the interrogation signal and in response to a voltage level representative of a predetermined amount of power received from the interrogation pulse signal, makes a temperature measurement and transmits a transponder response signal indicative of the temperature measurement. In addition, if the interrogation pulse is of longer duration than necessary to charge the transponder to the predetermined voltage, the remainder of the interrogation pulse is received, rectified and dissipated as heat, as shown in Figure 3. Figure 3 shows a voltage versus time diagram for a typical prior art RF-ID system. The power signal 44 of length  $t_2$  which is the amount of time it takes to power up the furthest transponder 48 in a given RF-ID system, is transmitted and the voltage versus time diagrams for the closest 46 and the furthest 48 transponders are shown underneath. The closest transponder 46 stores  $V_1$  amount of voltage, which is the amount of voltage required by the transponder to return a response, by time  $t_1$  which is a very small percentage of the duration of the interrogation signal. Therefore, from  $t_1$  to  $t_2$ , while the furthest transponder 48 is still charging up to the required voltage  $V_1$  and waiting for the end of the power burst signal, the closest transponder 46 is exposed to the same pulse and may heat up while it dissipates the excess energy of the interrogation signal. The excess energy being dissipated as heat by the close transponder 46 is indicated in the shaded region of the close transponders 46 voltage versus time diagram. There is little to no excess energy to be dissipated by the far transponder 48, as seen in its voltage versus time diagram, as transponder 48 requires all the energy absorbed to perform the temperature measurement, not impaired by heating-up effects, and transmit the transponder response signal.

However, in a preferred embodiment according to the invention, Figure 4 shows how varying the length of the interrogation pulse can charge-up transponders having a discharge function, located at different distances from the interrogator, to the same required voltage  $V_1$ , without the transponders having to dissipate extra interrogation signal as heat. For example, Transponder 1 is located just a short distance from the interrogator, therefore requiring only the minimum interrogation pulse duration  $t_1$  to achieve the required voltage  $V_1$  to transmit a response signal. Therefore, Transponder 1 receives the interrogation pulse of duration  $t_1$ , detects a decrease in the power level of the interrogation pulse and a voltage level  $V_1$ , representative of a predetermined amount of power received from the interrogation pulse signal, takes a temperature measurement and transmits a response signal. As

shown in Figure 4, Transponder 1 does not receive any excess interrogation signal which it must dissipate as heat. In a preferred embodiment of the invention, after sending a response signal, Transponder 1 is inactivated for a predetermined amount of time to allow the rest of the Transponders within a given interrogation range to respond. Therefore when the interrogator then transmits an interrogation pulse of duration  $t_2$ , Transponder 1 does receive the interrogation pulse but is inactivated and does not respond thus interfere with Transponder 2 signal. Instead, Transponder 2 receives the interrogation pulse of duration  $t_2$ , takes a temperature measurement and transmits a response signal under the same conditions as Transponder 1. Because interrogator 9 is transmitting successively longer duration interrogation pulses, instead of the maximum required duration pulses which would charge up the furthest transponder, Transponder 1, 2 and 3 are activated.

Although the transponders are receiving much closer to the exact amount of energy necessary to respond, there may still be some excess interrogation energy to dissipate, but just not nearly as much excess, especially for the transponders close to the interrogator. In a preferred embodiment according to the invention, transponder 25 performs temperature sensor functions via circuit element 38, and circuit element 38 also provides corrected temperature measurements which are corrected by an over-voltage compensating logic circuit, also a part of circuit element 38. Zener diode 34 and current sensor resistor 36 together form a current sensing over-voltage protection circuit. The value of zener diode 34 is chosen such that it will conduct when a higher voltage level exists than that representing the predetermined amount of power required to transmit a transponders response signal has been received from the interrogation signal. In other words, the conduction of the zener diode 34 signifies an over-voltage condition. Upon conduction of zener diode 34 and detection of such conduction by the current sensing element 36, a signal is transmitted from the current sensing element 36 to the temperature measurement compensating logic circuit of circuit element 38. The temperature measurement compensating logic circuit 38 receives a current level from the current sensing element 36 and combines this information with the amount of time elapsed from the start of current flow, then adjusts the temperature measurement accordingly, thereby compensating for the heat being generated by the excess energy of the interrogation pulse. Once the temperature measurement has been adjusted, the transponder response signal generator of circuit element 38 then transmits a response signal via antenna 26 back to the interrogator of Figure 1, wherein in one preferred em-

bodiment according to the invention, comprises an identification code and a heat compensated temperature measurement.

In another preferred embodiment according to the invention, instead of compensating for the inaccuracy of the temperature measurement, the temperature measurement is performed before the transponder has time to heat up. In other words, before the termination of the interrogation pulse, for example, in the first millisecond that a voltage level  $V_1$ , representative of a predetermined amount of power received from the interrogation pulse signal is detected, take the temperature measurement and then store the temperature measurement. After the transponder then detects a decrease in the power level of the interrogation signal, retrieve the temperature measurement and transmit the response signal back to the interrogator.

Another illustration of a preferred embodiment according to the invention comprising the interrogator 9 of Figure 1 and the Transponders 1, 2 and 3, which have a discharge function, of Figure 4, is illustrated in Figure 5. Interrogator 9 transmits a first minimum duration interrogation pulse of 5 msec in duration. Transponder 1 closest to the interrogator 9 charges up to the required voltage  $V_1$  with the first interrogation pulse and sends a response signal in return. After Transponder 1 transmits a response signal back to the interrogator 9, in a preferred embodiment, Transponder 1 is inactive to transmit another response signal for the predetermined amount of time that it takes for the remainder of the transponders in the interrogation range to respond. Therefore, when the interrogator 9 sends a second pulse of 5 msec, the same duration as the first pulse, the receiver 20 of the interrogator does not detect a response signal and the duration of the next interrogation pulse is increased via the Pulse Width Control Circuit 24. In the embodiment shown in Figure 5, the increase is shown to be double the original pulse width.

Transponders 2 and 3 are further from the interrogator and charge up partially from the first and second 5 msec interrogation pulses, but do not acquire the  $V_1$  volts required to return a response signal. Therefore, while Transponder 1, having received adequate energy from interrogation pulse of duration  $t_1$  to respond, is transmitting the response signal, Transponders 2 and 3 are discharging the amount of energy received from the interrogation pulse of duration  $t_1$ . Upon transmission of the interrogation pulse of 10 msec duration, Transponder 2 is charged up to a voltage of  $V_1$ , initiating a response signal, and subsequently inactivating Transponder 2. Again, the interrogator 9 transmits an interrogation pulse of 10 msec duration, and the receiver 20 of the interrogator does not detect a response signal and, in the embodiment shown, the

Pulse Width Control Circuit 24 doubles the duration of the next interrogation pulse to 20 msec. Transponder 3 is the furthest of the transponders from the interrogator 9, thus none of the first four interrogation pulses were of sufficient duration to charge Transponder 3 to the required voltage  $V_1$ . However, transmission of the interrogation pulse of 20 msec duration charged Transponder 3 to the voltage  $V_1$ , initiating a response signal, and subsequently inactivating Transponder 3.

Although Figures 4 and 5 show a preferred embodiment according to the invention relative to transponders which have discharge functions, Figure 6 shows a preferred embodiment of the invention relative to transponders which have no discharge function. The advantage of using transponders with no discharge function, is that the interrogation signal duration does not have to be increased to reach further and further transponders. In addition, the transponders after receiving any energy from an interrogation signal at all, retain a substantial amount of that energy, and add any new energy received from other interrogation pulses to that existing amount of energy. For example, Transponder 60 receives some energy from the first 5 msec, minimum duration, interrogation pulse, and substantially retains that energy. Upon reception of the second 5 msec duration interrogation pulse, Transponder 60 has acquired  $V_1$  volts of interrogation energy and is enabled to transmit a response signal. Transponder 62, which is further from the interrogator than Transponder 60, receives some energy from the first two 5 msec interrogation pulses, but because it is further from the interrogator than Transponder 60, Transponder 62 does not receive as much energy. However, the energy that Transponder 62 has received is retained and upon transmission of a third, 5 msec interrogation pulse, Transponder 62 also acquires  $V_1$  volts and transmits a response signal. Transponder 64, which is the furthest transponder from the interrogator, also receives and retains energy from the first three, 5 msec interrogation pulses and requires two more, 5 msec interrogation pulses before it has received the necessary  $V_1$  volts necessary to transmit a response signal.

Although Figure 6 shows that transponders with no discharge function, located at different distances from the interrogator 9, can be charged with a series of short, like duration interrogation pulses, the same transponders could be charged with a series of successively longer duration interrogation pulses, as shown in Figure 7. In this way, the interrogation process may be expedited by reaching more transponders simultaneously. Caution may be desired in the use of this interrogation method with transponders which have no discharge function because the benefits of increased range may be

offset by the amount of detrimental overages incurred in many of the transponders reached.

It is to be understood that doubling the duration of the interrogation pulse is one perturbation of many possible variations. For example, the pulse duration could be increased up to the 100 % represented by doubling the duration. Actually the increase could be even greater than 100%. As a more complicated example, there is oftentimes a given gaussian or bell shaped distribution of transponders in a given interrogation range. Therefore, instead of the interrogation pulses having double the duration or some other percentage increase, upon the absence of the response signal, the interrogator could have a circuit which would calculate the probability of a transponder falling within a certain range of the interrogator, and then calculate the required interrogation pulse duration to reach that transponder. Or, another alternative would be when sending an interrogation pulse which will potentially power-up many transponders, instead of calculating a specific interrogation pulse duration, increase the duration of the interrogation pulse in much smaller steps. This method would be similar to the way that digital transformations of analog data are done. When an analog signal is in a maximum, where there are many data points located in a small area, the digital steps are made very small to increase the accuracy of the measurement. In the same way, the power time control circuit 24 of the interrogator, could, when in the vicinity of a distribution maximum, make much smaller incremental changes in the duration of the interrogation pulse.

Furthermore, if the transponders do not have a discharge function and are located beyond the maximum in the distribution of transponders, chances are that they are very close to having the required voltage  $V_1$  necessary to send a response signal. Therefore, a decrease in the duration of the interrogation pulse may be necessary to charge-up the transponder without the risk of incurring a detrimental overage.

Figure 8 shows that in Automobile Vehicle Identification (AVI) applications involving high speed vehicles, the same types of over-voltage problems exist that are shown in the prior art voltage versus time function shown in Figure 3. An antenna 60 embedded in the road has the main lobe and side lobe field characteristics shown in the dotted lines. This field characteristic gives rise to three reading regions designated in the main lobe by "Region B" and the side lobes by "Region A". In the main lobe "Region B", the field strength is great and so a very short power pulse of length  $t_1$  is necessary to power up the transponder to the required voltage  $V_1$ . However, in the side lobes "Region A", there are not as many field lines so,

as shown in the graph of region "A", the pulse is not as strong and it takes a longer pulse of length  $t_2$  to charge-up the transponder to the required voltage  $V_1$ . Thus, an interrogator that sends longer pulse lengths to anticipate reading a car at the front of the antenna pattern, wastes a huge percent of the interrogation pulse upon entering the center of the antenna, because the transponder is charged up the the required voltage  $V_1$  quickly and then dissipates the greater portion of the interrogation pulse as heat. Therefore, the interrogator optimally sends longer duration pulses, for example 20 msec, when no response from a transponder is detected and the car is still approaching the antenna. However, upon detection of a transponder response signal, the interrogator transmits much shorter duration interrogation pulses, for example 5 msec, because the transponder has been charged by "Region A" of the antenna once and is now in "Region B" of the antenna. The interrogator continues to transmit short duration interrogation pulses until the interrogator does not detect a transponder's response for a predetermined amount of time, signifying the departure of the transponder from the range of the interrogation antenna. Upon the absence of the response signal, the interrogator transmits longer duration pulses again.

## Claims

### 1. An identification system comprising:

a transponder for receiving pulses of energy and then transmitting a response signal; and

an interrogator for transmitting a series of said interrogation pulses of energy ranging from pulses having a minimum duration to pulses having successively longer duration;

said interrogator further including a receiver for monitoring for said response signal for less duration than said transmitted interrogation pulse of minimum duration, subsequent to the transmission of said interrogation pulse and a pulse width control circuit such that in the absence of said transponder transmitting said response signal, said interrogator transmits an interrogation pulse having longer duration.

### 2. The identification system of Claim 1, wherein said interrogator further comprises:

an oscillator for generating said interrogation signal,

said pulse width control circuit being connected to said oscillator for determining the pulse duration of said interrogation signal,

an antenna connected to said oscillator for transmitting said interrogation signal and receiving said response signal,

a receiver connected to said antenna for emitting a control signal in response to the absence of said response signal,

a data control circuit connected to said receiver for sending an activating signal to said pulse width control circuit in response to said control signal, wherein said pulse width control circuit increases the duration of said interrogation pulse in response to said activating signal.

### 3. The identification system of Claim 1, wherein said transponder, subsequent to the transmission of said message, is inoperable to transmit another message for a predetermined amount of time.

### 4. A remote sensor system comprising:

an interrogator for transmitting a series of pulses of energy ranging from pulses having a minimum duration to pulses having successively longer duration;

a transponder for receiving said pulses of energy and storing said pulses of energy up to a predetermined amount of voltage, and dissipating the remainder of said pulses as heat, thereby indicating an over-voltage condition, and for sensing an environmental condition and for transmitting a response signal,

said transponder further comprising over-voltage protection circuitry and compensatory logic circuitry such that in response to said over-voltage condition, said compensatory logic circuitry compensates said sensed environmental condition for said over-voltage condition.

### 5. The remote sensor system of Claim 4, wherein said response signal comprises an identification code and said compensated environmental condition.

### 6. A method of interrogation in a communication system comprising an interrogator, which transmits an interrogation signal, and transponders, which receive the interrogation signal and transmit a response signal, comprising the steps of:

generating a first interrogation signal comprising a minimum duration pulse;

transmitting said minimum duration pulse;

monitoring for a response signal and in the absence of said response signal, increasing the pulse duration of said interrogation signal; and

repeating said generating, transmitting, monitoring and increasing steps until said response signal is detected.

7. The method of claim 6, wherein the monitoring step is performed by a receiver in the interrogator.
8. The method of Claim 7, wherein said increasing step comprises the steps of:
  - transmitting a control signal from said receiver to a data control circuit;
  - transmitting an activating signal from said data control circuit to a pulse width control circuit in response to said control signal; and
  - increasing the pulse duration via said pulse width control circuit in response to said activating signal.
9. The method of Claim 7, wherein said generating step is performed by an oscillator in said interrogator.
10. The method of Claim 7, wherein said monitoring for a response signal occurs for a predetermined duration.
11. The method of Claim 10, wherein said predetermined duration is of shorter duration than said minimum duration interrogation pulse.
12. A remote identification and sensor system comprising:
  - an interrogator for transmitting an interrogation signal;
  - a transponder for receiving an interrogation signal, for performing a sensor measurement and for transmitting a response signal in response to said interrogation signal comprising:
    - an antenna for receiving said interrogation signal and for transmitting said response signal in response,
    - a rectifying element connected in series with said antenna for rectifying said interrogation signal,
    - a storage element connected in series with said antenna for storing a predetermined amount of said rectified interrogation signal,
    - a current sensing over-voltage protection circuit connected in parallel with said series combination of said antenna and said storage element comprising, a series combination of an over-voltage protection element and a current sensing element, and
    - a circuit element for making a sensor measurement, and for compensating said sensor measurement, and for generating a response signal, having two inputs with one input connected in series with said rectifying element and the second input connected between said over-voltage protection element and said current sensing element.
13. The system of Claim 12, wherein said circuit element further comprises a logic circuit for compensating said sensor measurement.
14. The system of Claim 13, wherein said current sensing element, in response to current flow through said current sensing element, provides a signal proportional to the amount of current sensed to said logic circuit.
15. The system of Claim 14, wherein said current sensing element detects said current flow upon conduction of said over-voltage protection element.
16. The system of Claim 15, wherein said over-voltage protection element conducts in response to said storage element having greater than said predetermined amount of rectified interrogation signal stored.
17. The system of Claim 13, wherein said sensor measures temperature.
18. The system of Claim 13, wherein said temperature compensating performed is a decrease in the measured temperature.
19. The method of remotely sensing an environmental condition comprising the steps of:
  - receiving an interrogation pulse of a predetermined duration for providing power;
  - rectifying said interrogation pulse subsequent to receiving said interrogation pulse;
  - storing said rectified interrogation pulse up to a predetermined amount of voltage subsequent to rectifying said interrogation pulse;
  - detecting said predetermined amount of voltage, subsequent to storing said rectified interrogation pulse;
  - immediately measuring said environmental condition, in response to said detection of said predetermined amount of voltage, subsequent to detecting said predetermined amount of voltage;
  - storing said measured environmental condition, subsequent to measuring said environmental condition;
  - detecting a decrease in the power level of said interrogation pulse, subsequent to storing said environmental condition;
  - retrieving said measured environmental condition;
  - transmitting a response signal in response to said detection of said predetermined amount of voltage and said decrease in said power level of said interrogation pulse.

20. An identification system comprising:  
a transponder for receiving pulses of energy and then transmitting a response signal;  
and  
an interrogator for transmitting a series of  
said interrogation pulses of energy ranging  
from pulses having a minimum amplitude to  
pulses having successively greater amplitudes;  
said interrogator further including a receiver for monitoring for said response signal subsequent to the transmission of said interrogation pulse and an amplitude control circuit such that in the absence of said transponder transmitting said response signal, said interrogator transmits an interrogation pulse having greater amplitude.
21. A transponder for an identification system as claimed in any of claims 1, 2, 3 and 20 or for a remote sensor system as claimed in any of claims 4, 5, 12, 13, 14, 15, 16, 17 and 18.
22. A receiver for an identification system as claimed in any of claims 1, 2, 3 and 20 or for a remote sensor system as claimed in any of claims 4, 5, 12, 13, 14, 15, 16, 17 and 18.
23. An identification system comprising:  
a transponder for receiving pulses of energy and then transmitting a response signal;  
and  
an interrogator for transmitting a series of  
said interrogation pulses of energy ranging  
from pulses having a minimum energy to  
pulses having successively greater energy;  
said interrogator further including a receiver for monitoring for said response signal subsequent to the transmission of said interrogation pulse and a control circuit such that in the absence of said transponder transmitting said response signal, said interrogator transmits an interrogation pulse having greater energy.
